

PTPN11 — transcript-model comparison (differences only)

Homo Sapiens · 5 of 5 protein model(s) shown · primary NP_001317366.1 first · 5 of 56 alternative-model exons differ from the primary

Which coding exons do the alternative protein models share with the primary, and where do they diverge? Exon identity is compared on genomic CDS coordinates, so an upstream deletion does not mark genomically identical downstream exons as altered. Differences are annotation differences, not validated splicing events.

- coding exon of the primary model
- shared genomic exon (identical CDS interval)
- shifted exon boundary (same exon, different CDS end)
- missing protein region (primary exon not used)
- alternative terminus
- exploratory candidate region (not validated)
